20. ABSTRACT (Continue on reverse side if necessary and identify by block number) Results are presented for the blast loading of construction materials and closure designs for basement shelters. Blast loading histories and the corresponding panel displacements are presented for three types of closure designs: plywood sheet panels, wood beam panels, and plywood stressed skin panels. Ultimate failure loads were determined for the three closure designs.

SUMMARY

I. INTRODUCTION

The experiments reported here are a part of a study funded by the Defense Civil Preparedness Agency under project No. DCPA 01-78-C-0247, Work Unit 1123-C, entitled "Blast Loading in Existing Structures." The purpose of this part of the study was to determine the ultimate failure under air blast loads of construction materials and closure designs. Data are given for plywood sheets panels, wood closures, and plywood stressed skin panel closures (PSSP).

II. EXPERIMENT

Panels of sheet plywood (1.27 cm to 2.54 cm thickness) were simply supported at two ends and loaded by the blast at the end of the Ballistic Research Laboratory's 57.5 cm I.D. shock tube. A second and third series of tests were completed in a similar manner with wood beams made of 2x's placed flat, and the PSSP closures. Pressure-time loading and displacement histories were measured as a function of the blast wave for the different closures.

III. RESULTS AND CONCLUSIONS

Records of blast wave loading and panel displacement are presented as plots in the body of this report.

Panel displacement amplitudes and frequencies are presented as a function of closure type. The loads needed for ultimate failure of the closures exposed to blast was about 4-20 times the allowable static load.

I. INTRODUCTION

The work reported here is a part of a task at the Ballistic Research Laboratory (BRL) funded by the Civil Preparedness Agency (DCPA) under project Order No. DCPA 01-78-C-0247, Work Unit 1123-C entitled "Blast Loading in Existing Shelter Structures." The purpose of the present work is to verify the prediction of the loads needed to cause ultimate failure (breakout) in predesigned closures intended to upgrade existing basement shelters.¹

Three kinds of closures were to be tested to breakout: plywood sheet panels, wood beam closures (2x's placed flatwise), and plywood stressed skin panels (PSSP). The test procedure used was to blast load the simply supported closures at the end of the shock tube until breakout occurred. The experimental setup is described below.

II. EXPERIMENT

The shock tube, panel test fixture, and recording instrumentation are briefly described in this section.

A. Shock Tube Setup

A panel holder was constructed for use at the end of the BRL 57.5 cm I. D. shock tube. The test fixture which had been used to hold the plywood panels in the previously reported experiments² was modified for these tests.

Figure 1 shows the panel holder at the end of the shock tube; Figure 2 shows some additional details of the setup.

Each panel was simply supported at two ends. Figures 3-5 show the panel sizes and construction details. To allow free movement through the 47 cm square opening, a small clearance of 0.315 cm was allowed on the long sides, between the panel and the holder. A strip of 0.317 cm thick rubber was attached to the holder on each side so as to overlap the clearance openings. The rubber was left loose at each side of the test panels and could move freely with the panel when blast

loaded. Two small finishing nails (1.44 mm dia x 38.1 mm long - 4d) were driven into the bottom of the panels to assure the proper stand-off (1.27 cm or 0.64 cm depending on the test panel length). Rubber bands were used to hold the panel in contact with the holder to assure no air loss during loading.

The test setup was completed with a high speed camera, pressure transducer, and displacement follower. These are described in Section B below.

B. Instrumentation

The pressure recording consisted of a PCB Model 113 M 28 quartz transducer with a built-in voltage amplifier. The signal from the transducer was recorded by an FM Honeywell 7600 tape recorder. A quick-look oscillograph playback was available at the test site to view the records until the analog data could be converted to digital, and be plotted with engineering units.

The displacement data was acquired with an OPTRON Model 501 Electro Optical Displacement Follower³. A small black balsa wood target, glued to outside of the panel, was tracked with the displacement follower. The optical target image was converted to an electron image in which the electron density was proportional to the corresponding light (from target) intensity. Again the electrical output signal was recorded by the 7600 FM tape machine. The data reduction method was the same as that for the pressure records.

A high speed camera (Red Lakes Hycam) running at 5000 pps completed the instrumentation. During the tests the lighting was found to be inadequate for the desired framing rate. Therefore, the camera was not used after the initial checkout shots and no prints will be shown.

III. RESULTS

The results are presented in two sections: The pressure loading and displacement traces, and a summary data table.

A. Pressure and Displacement Traces

A typical series of loading and deflection records are shown in Figures 6-11. The pressure-time records show the input shock wave

as it passes the transducer station and then the reflected pressure (at 2-3 ms) back from the loaded test panel. If the panel was broken out during the shock pressure loading period a rarefaction decay is shown. See the bottom trace of Figure 8 (Cont) as an example.

The displacement records show the center panel amplitude displacement as a function of the reflected shock wave load and the accompanying oscillations. As the load on a test panel was increased, the average deflection increased but the oscillation tended to be damped. As the panel began to crack and finally to blow out the optron follower was no longer able to follow the displacement. See Figure 7 - bottom trace. Other records for the remaining shots are given in the appendix to this report.

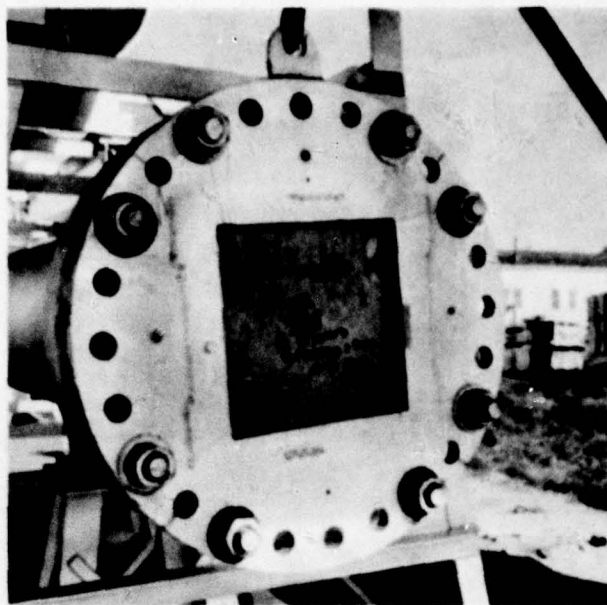

Figures 12-17 show cases of panel damage - from slight cracks as shown in Figure 12 to near total blow-out as seen in Figure 15.

B. Data Tables

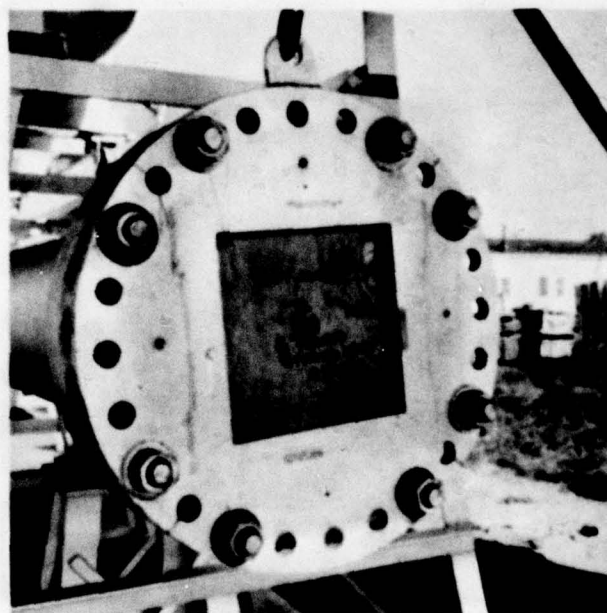

The results of the blast exposed panels are given in Tables 1 and 2. The first table groups the results obtained for the tests on the plywood sheet closures. The panels listed were all made of a single sheet of plywood. Most were exposed only one time. A letter after the shot number does mean multiple exposure. Multiple shots were used during the testing if there was no visible damage to the panel, no cracking at all. The plywood panels showed slight damage for loads below the ultimate failure level - then at the out point complete breakout would occur. The load values near to breakout and at breakout were averaged to give the value for ultimate failure used to compare with predicted values in the analysis section.

The second table summarizes the results from the wood beam closure of 2x's placed flat and the plywood stressed skin panels tested as closures. Here again the test results were similar to those for plywood sheets in that at first slight damage only occurred, then complete breakout as the load was increased. The ultimate failure point was found to be somewhat higher for the PSSP panels when the skins were glued and nailed than for the unglued skins. The difference was not very great, approximately, 7 kPa.

The 2x's placed flat showed a smooth linear displacement as the blast load was increased, then some yield took place, and then blowout occurred. Figure 18 is a plot from the listed table data for the 2x's used for closures. Breakout occurred at about 31.4 kPa (4.5psi) for 1.27 cm plywood, at 90.4 kPa (13.1 psi) for 1.59 cm plywood, at 74.2 kPa (10.8 psi) for 1.90 cm plywood, and at 124.3 kPa (18.0 psi) for the 2.54 cm plywood. For the closure made of flat 2x's the breakout occurred at about 488 kPa (70.8 psi). The PSSP closures blowout

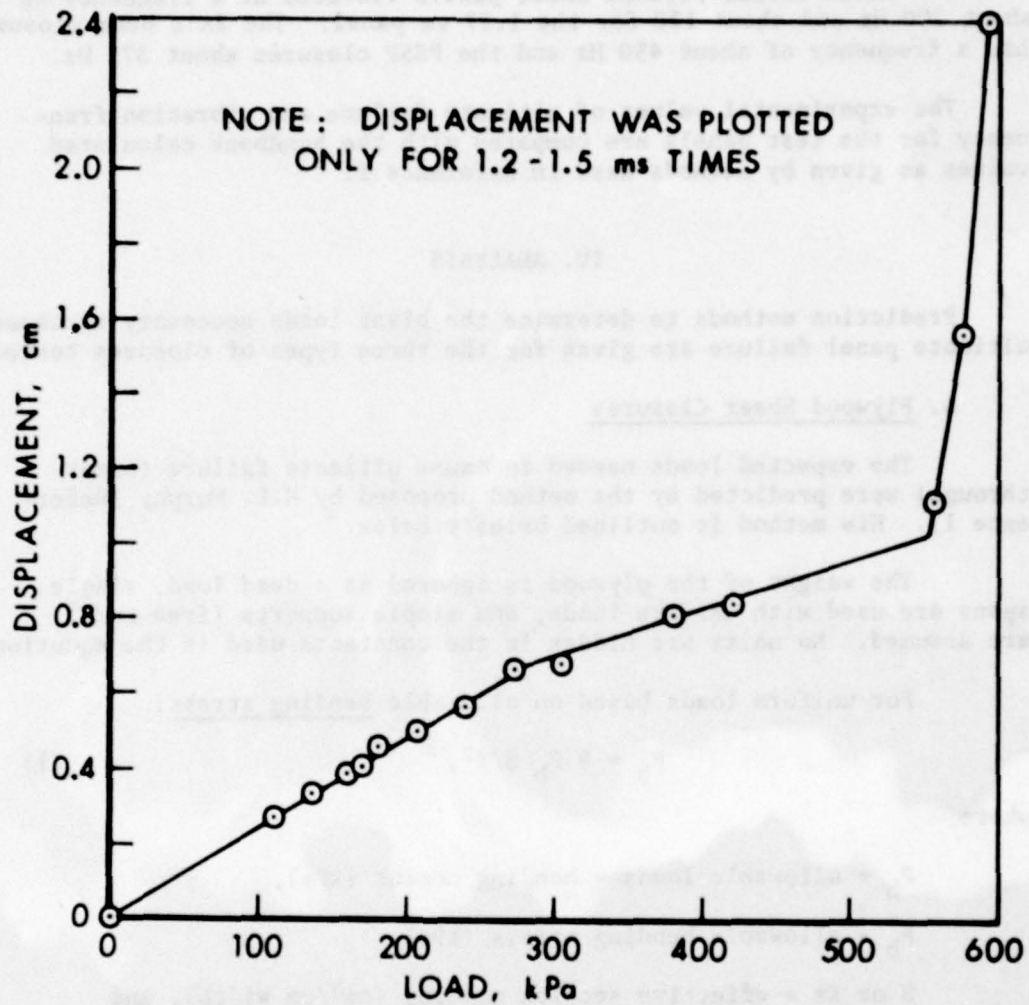

Figure 18. Displacement load, kPa as a function of load for flat 2x's

(plywood skins) at about 147 kPa (21.3 psi) for skins nailed only and 154 kPa (22.3 psi) for nailed and glued plywood skins. The glue seemed to have added some small amount of additional strength. The whole panel, including stringers, seems to blow out when the skins were only nailed. The skins broke out when they were glued and nailed.

The three larger plywood sheet panels vibrated at a frequency of about 200 Hz and about 120 for the 1.27 cm panel. The 2x's beam closure had a frequency of about 450 Hz and the PSSP closures about 375 Hz.

The experimental values of ultimate failure and vibration frequency for the test panels are compared with the handbook calculated values as given by methods used in Reference 1.

IV. ANALYSIS

Prediction methods to determine the blast loads necessary to cause ultimate panel failure are given for the three types of closures tested.

A. Plywood Sheet Closures

The expected loads needed to cause ultimate failure (break-through) were predicted by the method proposed by H.L. Murphy (Reference 1). His method is outlined briefly below.

The weight of the plywood is ignored as a dead load, single spans are used with uniform loads, and simple supports (free ends) are assumed. No units are hidden in the constants used in the equations.

For uniform loads based on allowable bending stress:

$$P_b = 8 F_b S / l^2, \quad (1)$$

where

P_b = allowable loads - bending moment (kPa),

F_b = allowable bending stress (kPa),

S or K_s = effective section modulus (cm^3/cm width), and

l = clear span (cm).

For uniform loads based on allowable rolling shear stress:

$$P_{st} = 2 F_s (I_b/Q) / l, \quad (2)$$

where

P_{st} = allowable load-rolling shear stress (kPa),

F_s = allowable rolling shear stress (kPa),

(Ib/Q) = rolling shear constant (cm^2/cm width), and

l = clear span (cm).

The useful allowable load P_m becomes:

$$P_m = P_b \text{ or } P_{st}, \text{ whichever is smaller (kPa).} \quad (3)$$

For the present test panels $P_m = P_b$.

A ductility factor is included to give:

$$P_{dm} = 5/6 P_m: \quad (3a)$$

For bending deflection (elastic) under uniform load:

$$Y_b = P_m l^4 / (76.8 I (1.1E)) \quad (4)$$

where

Y_b = bending deflection (elastic) under uniform load (cm),

I = effective moment of inertia (cm^4/cm width),

E = modulus of elasticity (kPa), and

l = clear span (cm).

For shear deflection (elastic) under uniform load:

$$Y_s = P_m C t^2 l^2 / (106 E I), \quad (5)$$

where

Y_s = shear deflection (elastic) under uniform load (cm),

C = 120 or 60 for panels applied with face grain perpendicular to or parallel to supports, respectively, and

t = nominal panel thickness (cm).

For combined bending and shear deflection (elastic) either add Y_b and Y_s from Equations 4 and 5 or use Equation 4 only with the constant 1.1 dropped from the equation.

For the plywood bearing face under uniform load (ends over simple supports):

$$l_e = l / (2((F_{cl} / P_m) - 1)), \quad (6)$$

where

l_e = required plywood end bearing length at each end of panel (cm), and

F_{cl} = allowable bearing stress on the plywood face, for load perpendicular to plane of outer ply actually in bearing (kPa).

Reference 1 recommended that l_e be at least 3.8 cm; this recommendation was followed for the plywood panels just tested.

Ultimate failure for the panels was calculated by using values furnished in Reference 4, of materials strength parameters (Table 3), to give the allowable loads. These values were then corrected for the ductility ratio and multiplied by a factor of four as suggested by Murphy (Reference 1) to give the expected blast load needed to cause ultimate failure of the closures. Table 4 lists the predicted values.

B. Wood Beam Closures

Again the predictions of ultimate loads to fail the wood beam closures follow the methods of Murphy (Reference 1). The assumptions are the same as for the plywood closures.

The flexural or bending resistance is calculated from Equation 7:

$$q_b = 0.5 F_b (d/l)^2 / (3c), \quad (7)$$

where

F_b = extreme fiber stress in bending (kPa),

l = clear span (cm),

d = thickness (depth) of beam (cm), and

c = 1/8 for simply supported beams.

⁴"Plywood Design Specification," American Plywood Association, P.O. Box 2277, Tacoma, Wash. 98401, December 1976.

					154	

Note: all closures tested had a free span, l , of 39.37 cm.

The horizontal shear resistance is found from Equation 8:

$$q_v = 2F_v d / (3c'(\ell - 2d)), \quad (8)$$

where

F_v = horizontal shear stress (kPa),

ℓ = clear span (cm),

d = thickness (depth) of beam (cm), and

$c' = 1/2$ for simply supported beams.

The wood beam resistance, q , is then equal to lesser value of q_b and q_v .

$$q = \text{least of } q_b \text{ and } q_v. \quad (9)$$

The air blast load to cause ultimate failure is found from Equation 10:

$$P_m = 4(1 - 1/(2\mu))q, \quad (10)$$

where the design ductility ratio $\mu = 3$, and

$$P_m = 4(5/6)q. \quad (11)$$

The required bearing length at each end is:

$$\ell_e = q\ell c' / F_{cl} \quad (12)$$

where

ℓ = clear span (cm),

F_{cl} = compression stress perpendicular to grain or bearing stress (kPa), and

$c' = 1/2$.

ℓ_e is recommended to be at least 3.81 cm.

The calculated load to cause ultimate failure for the wood beam closure (2x's placed flat), after multiplying the least allowable load, q_v , by the ductibility ratio and by a factor of 4, is given in Table IV.

B. Plywood Stressed-Skin Panel Closures

The analysis of the plywood stressed-skin panel closures (PSSP) again follows closely that given in Reference 1. The panels are assumed to be uniformly loaded with the outer plies of the two plywood skins to be parallel to the stringers.

A view of the end section of the PSSP closure to be tested is shown in Figure 19. The clear distance between stringers should be less than twice the basic spacing, b , as given in Table 5, for these calculations to apply. See Figure 19A.

The neutral axis (N.A.) is calculated by following the steps of Figure 19A. A value of EI_g , the stiffness factor, is calculated for the combined skins and stringers of the test panel, Figure 19B.

The allowable load in panel deflection is:

$$P_d = 1/(C\ell\ell'(\frac{5}{384} \frac{\ell^2}{EI_g} + \frac{0.15}{AG})) + DL \quad (13)$$

where

P_d = allowable total load-panel deflection (kPa),

C = factor for maximum allowable deflection - 360 for floors, 240 for roofs,

EI_g from Figure 19 (kPa - cm^4),

A = actual total cross section area of all stringers (cm^2),

G = modulus of rigidity of stringers (kPa) taken as 0.06 (1.03E),

ℓ = clear span of panel in direction of stringers (cm), and

ℓ' = width of panel - for skins in direction perpendicular to ℓ (cm).

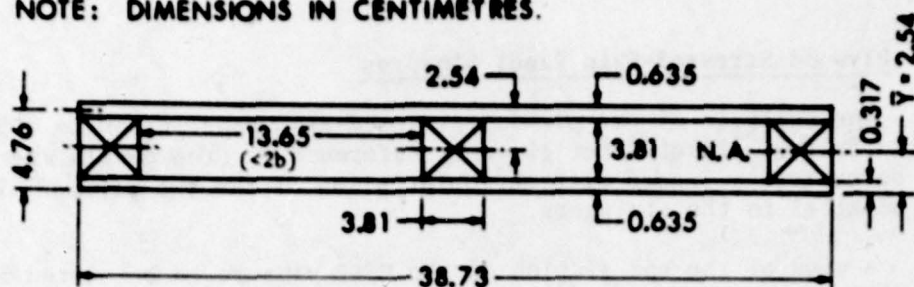

The dead weight (DL) is zero for the present test panel since each panel was loaded as a wall panel, (upright position), not as a floor panel.

$P_d = 117.6$ kPa (17.1 psi) for the PSSP tested - the allowable total load for panel deflection.

The allowable total load - top skin deflection (cross panel), is:

$$P_t = 384 EI/(c(\ell'')^3) + DL, \quad (14)$$

NOTE: DIMENSIONS IN CENTIMETRES.

2.86 (2-4-1)					142

* Where plywood face grain is across stringers, write APA for appropriate "B" distances.

where

P_t = allowable total load - top skin deflection (kPa),

C = factor for maximum allowable deflection - 360 for floors and 240 roofs,

E is for top skin (kPa),

I = stress applied perpendicular to stringer and face grain (cm^4/cm),

l'' = clear distance between stringers (cm), and

l''/C = midspan deflection (cm).

when DL is zero $P_t = 7.28$ kPa (1.06 psi) for the top skin of the panel tested.

The total allowable load in bending is found from Equation 15:

$$P_b = (8F/c l' l^2) (EI_n / E_{\text{skin}}), \quad (15)$$

where

P_b = allowable load in bending (kPa) where EI_n is for bending about a neutral axis, calculated as in Figure 19 but with the effective width of bottom skin to be used. For the present test, panel spacing $l' \leq b/2 + \text{stringer width}$ (the effective width), and therefore

$EI_n = EI_g$ as already calculated ($\text{kPa} - \text{cm}^4$).

$F = F_c$ or F_t (F_c for top skin and F_t for bottom skin) (kPa).

The values of F_c and F_t are to be corrected in the following way:

if $\frac{l''}{b} = \leq 0.5$ use 100% of F_c and F_t ,

if ratio ≥ 1.0 to 2 use 67%, and for ratios between 0.5 and 1 vary percentage linearly between 100 and 67%.

E = skin under check including percentage increase (kPa),

c = distance to center of skin thickness from N.A (cm), and

l and l' are as before (cm).

The values of P_b are 80.0 kPa (11.6 psi) using upper skin and 85.7 kPa (12.4 psi) using bottom skin of the test panel.

The allowable total load - rolling shear is:

$$P_{st} = (2(\sum F_s t) / (\ell \ell' Q_s)) (EI_g / E_{skin}) \quad (16)$$

where the statical moment

$$Q_s = A d_s \text{ and} \quad (17)$$

$$d_c = c - y', \quad (18)$$

See Figure 20 for definition and value of y' (Table 6). $\sum F_s t$ (kPa-cm) is the sum of the glue-line widths over each stringer (three in test panel) multiplied by its applicable allowable rolling shear stress F_s (Table 3 above). ℓ and ℓ' (cm) are same as before. $P_{st} = 43.2$ kPa (6.3 psi) for the test panel.

The allowable total load - horizontal shear is:

$$P_v = (2(\sum F_v t) / \ell \ell' Q_v) (EI_g / E_{st}), \quad (19)$$

where

P_v = allowable load - horizontal shear (kPa),

F_v = allowable stress in stringer horizontal shear (kPa),

t = sum of stringer width (cm),

EI_g is from Figure 12 above (kPa - cm⁴),

E_{st} is for stringer including percentage (3%) increase (kPa),

ℓ and ℓ' as before (cm), and

$$Q_v = Q_{\text{stringer}} + Q_{\text{skin}} (E_{\text{skin}} / E_{\text{stringer}}). \quad (20)$$

The terms of Q_v are:

$Q_{\text{stringers}}$ = cross section of all stringers either above or below N. A. times its centroidal distance from N.A. (cm³),

$Q_{\text{skin}} = A_{11}$ for chosen skin times moment arm (cm³), and

E 's are as before (with percentage increases) (kPa).

The value calculated for P_v is 28.4 kPa (4.13 psi) for the panel tested.

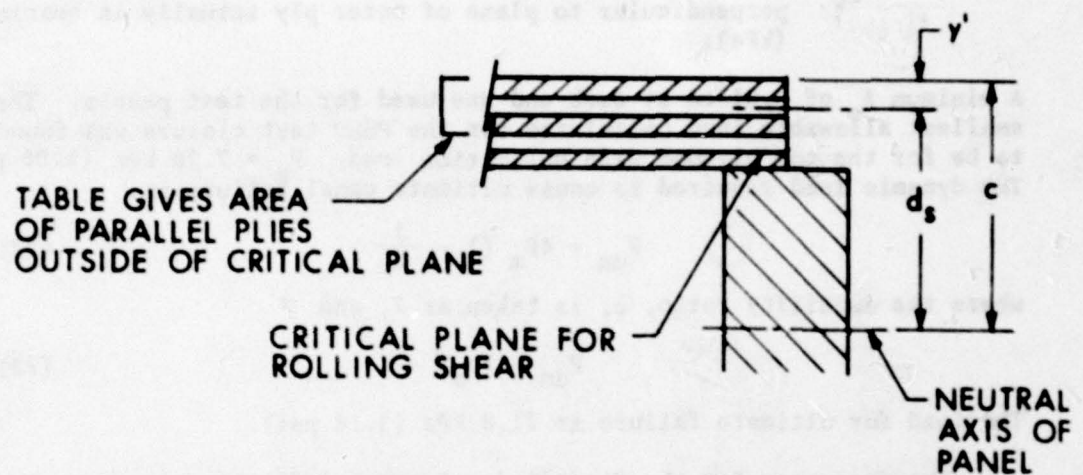

Figure 20. Rolling shear critical plane and Q_s .

The minimum bearing length at each end is:

$$l_e = P_m l / (2 F_{cl}), \quad (21)$$

where

l_e = required plywood end bearing length at each end of the panel (cm),

l = clear span (cm),

l' = full panel width (skins) (cm),

P_m = smallest of calculated allowable loads (kPa), and

F_{cl} = allowable bearing stress on plywood face, for load perpendicular to plane of outer ply actually in bearing (kPa).

A minimum l_e of 3.81 cm at each end was used for the test panels. The smallest allowable load calculated for the PSSP test closure was found to be for the top plywood skin deflection load, $P = 7.28$ kPa (1.06 psi). The dynamic load required to cause ultimate panel failure is:

$$P_{dm} = 4P_m \left(1 - \frac{1}{2\mu}\right) \quad (22)$$

where the ductility ratio, μ , is taken as 2, and

$$P_{dm} = 3P_m. \quad (23)$$

The load for ultimate failure is 21.8 kPa (3.16 psi).

The frequency for the first mode of panel deflection is given by Equation 24 (Reference 5). The panel is assumed to act like a simply supported beam (free at each end) which is uniformly loaded.

$$f = \frac{50\pi}{l^2} \sqrt{\frac{EI}{\Delta W}} \quad (24)$$

where

f = frequency of first mode (Hz),

l = free span of panel (cm),

⁵ Lionel S. Marks, Editor, "Marks' Mechanical Engineers' Handbook", MacGraw-Hill Book Co., Inc., New York, NY, 1951.

HI = flexural rigidity of panel (kPa-cm⁴/panel width)

A = cross section area of panel or component (cm),

W = weight of panel or component (gm/cm³).

I is calculated from Equation 25 for all closures except PSSP closure:

$$I = \frac{w d^3}{12}, \quad (25)$$

where

w = width of panel (cm) and

d = thickness of panel (cm).

EI = EI_g from Figure 19 was used in calculations for PSSP closure.

The calculated and experimental values for P_{dm} and f for each type of closure tested are listed in Table IV. for comparison.

V. SUMMARY AND CONCLUSIONS

As a part of a program to upgrade existing shelters, the Defense Civil Preparedness Agency has had a design manual (Reference 1) prepared which describes and lists pre-designed closures. Three types are listed: plywood sheet closures, wood beam closures, and plywood stressed skin panels to be used as closures. The closures are designed to be placed in basement shelter openings - windows and entryways, for example. The intent was to use these pre-designed closures to upgrade home and commercial basements to resist increased levels of blast pressure over the shelters' present ability to protect the shelterees.

The design procedures followed in Reference 1 was to calculate the allowable static load (minimum value used if more than one) and to correct this value to a dynamic load for ultimate failure for each closure. The present work was done to verify experimentally the values of ultimate failure predicted for the closures.

The three types of closures were exposed to the loading of reflected shock overpressures at the end of the BRL 57 cm shock tube. Plywood sheet panels of various thickness (1.27, 1.59, 1.90, and 2.5 cm) were loaded to bursting while simply supported at two ends. Wood beam panels (2x's placed flat) and plywood stressed skin panels were tested in the same way. Input shock pressure and center-point panel deflection data were obtained for the different test panels.

Loading data - pressure load, panel deflection, and panel vibration frequency were listed and compared to the calculated values. Bursting loads were found to be about four times the predicted allowable load for the plywood sheet closures. The factor was about six times for the beam closures and over twenty times for the plywood stressed skin panels. The plywood skin was the weaker element in the PSSP panels as predicted but the skin was still many times stronger than it was calculated to be.

Accordingly, all the pre-designed closures as listed in Reference 1 appear to be stronger (loaded to ultimate failure) by a factor of 2-7 times than was predicted for ultimate failure.

Again, as seen in earlier experiments with closures simply supported on four sides (Reference 2), damage was light until the bursting point was reached. The panel would nearly always blow out completely when the plywood sheet closures failed. The beam closures lost one or more beams and the PSSP closures lost a great part of their skins during failure. At loads higher than burst pressure the entire panel burst into many fragments.

In general all panels tested took loads that exceeded the predicted load for ultimate failure as pre-designed.

ACKNOWLEDGMENTS

The author wishes to thank Messrs. Kenneth Holbrook and Vincent King for the careful experimental work performed at the BRL Shock Tube Facility.

LIST OF SYMBOLS

A	Cross section area, cm^2
b	Basic stringer spacing, cm
C, C'	Constants, no units
d	Thickness (depth) of beam, cm
E	Modulus of elasticity, kPa
EI	Flexural rigidity, kPa - $\text{cm}^4/\text{width panel}$, cm
E _{st}	Modulus of elasticity of stringers, kPa
F _b	Allowable bending stress, kPa
F _c	Allowable bending stress - top skin, kPa
F _{cl}	Allowable bearing stress - load perpendicular to plane of outer ply or grain actually in bearing, kPa
F _s	Allowable rolling shear stress, kPa
F _v	Horizontal shear stress, kPa
f	Frequency, Hz
G	Modulus of rigidity, kPa
(Ib/Q)	Rolling shear constant, $\text{cm}^2/\text{cm width}$
l	Clear span, cm
l _e	Required end bearing length, cm
l _e ^q	Width of panel skin, cm
l''	Clear distance between stringers, cm
l''/C	Midspan deflection, cm
P _b	Allowable load - bending moment, kPa
P _d	Allowable load - panel deflection, kPa
P _m	Allowable load - corrected for ductility ratio, kPa
pps	Pictures per second
P _{st}	Allowable load - rolling shear stress, kPa
P _t	Allowable load - top skin deflection, kPa
P _v	Allowable load - horizontal shear, kPa
P _{qt}	Allowable load - top skin deflection, kPa
Q _v	Statical moment, cm^3
q _b	Flexural or bending resistance, kPa
S or KS	Effective section modulus, $\text{cm}^3/\text{cm width}$
t	Sum of stringer width, cm
μ	Ductility ratio, no units
W	Weight of panel, gm/cm^3
w	Width of panel, cm.
Y _b	Bending deflection (elastic) under uniform load, cm
Y _s	Shear deflection (elastic) under uniform load, cm

USER EVALUATION OF REPORT

Please take a few minutes to answer the questions below; tear out this sheet and return it to Director, US Army Ballistic Research Laboratory, ARRADCOM, ATTN: DRDAR-TSB, Aberdeen Proving Ground, Maryland 21005. Your comments will provide us with information for improving future reports.

1. BRL Report Number _____

2. Does this report satisfy a need? (Comment on purpose, related project, or other area of interest for which report will be used.)

3. How, specifically, is the report being used? (Information source, design data or procedure, management procedure, source of ideas, etc.) _____

4. Has the information in this report led to any quantitative savings as far as man-hours/contract dollars saved, operating costs avoided, efficiencies achieved, etc.? If so, please elaborate.

5. General Comments (Indicate what you think should be changed to make this report and future reports of this type more responsive to your needs, more usable, improve readability, etc.) _____

6. If you would like to be contacted by the personnel who prepared this report to raise specific questions or discuss the topic, please fill in the following information.

Name: _____

Telephone Number: _____

Organization Address: _____
